A Digital signal processor selectively demodulates and decodes signals received from multiple types of transmission channels such as satellite, terrestrial and cable transmission channels. A received signal is representative of compressed digital video information such as television picture information, and is encoded in one of a plurality of coding formats (e.g., trellis or punctured codes of selectable code rate). The received signal is also modulated in one of a plurality of modulation formats (e.g., PAM, QAM or PSK). A demodulator selectively demodulates the signal modulated in one of the plurality of modulation formats, and a decoder selectively decodes the demodulated signal coded in one of the plurality of coding formats.

(57) A Digital signal processor selectively demodulates and decodes signals received from multiple types of transmission channels such as satellite, terrestrial and cable transmission channels. A received signal is representative of compressed digital video information such as television picture information, and is encoded in one of a plurality of coding formats (e.g., trellis or punctured codes of selectable code rate). The received signal is also modulated in one of a plurality of modulation formats (e.g., PAM, QAM or PSK). A demodulator selectively demodulates the signal modulated in one of the plurality of modulation formats, and a decoder selectively decodes the demodulated signal coded in one of the plurality of coding formats.

ABSTRACT OF THE DISCLOSURE

A Digital signal processor selectively demodulates and decodes signals received from multiple types of transmission channels such as satellite, terrestrial and cable transmission channels. A received signal is representative of compressed digital video information such as television picture information, and is encoded in one of a plurality of coding formats (e.g., trellis or punctured codes of selectable code rate). The received signal is also modulated in one of a plurality of modulation formats (e.g., PAM, QAM or PSK). A demodulator selectively demodulates the signal modulated in one of the plurality of modulation formats, and a decoder selectively decodes the demodulated signal coded in one of the plurality of coding formats.

APPARATUS FOR DEMODULATING AND DECODING SATELLITE,
TERRESTRIAL AND CABLE TRANSMITTED DIGITAL TELEVISION
DATA

This application is a division of Canadian Serial No. 2,161,467 filed
October 26, 1995.

The invention is related to the field of digital signal processing
apparatus suitable for use in a multi-channel receiver of satellite, terrestrial
5 and cable transmitted digital television data.

BACKGROUND OF THE INVENTION

Known in the art is the use of forward-error-correction that includes
convolutional encoding in the transmission of encoded digital data over a
noisy channel from a transmitter to a receiver that includes a branch metric
10 computer for a Viterbi-algorithm based convolutional decoder. The Viterbi
Algorithm is used very commonly to decode a convolutionally encoded
sequence of bits transmitted over a noisy channel. In the heart of the Viterbi
algorithm is a series of repetitive add-compare-select operations which accept
as input certain metrics (termed branch metrics) computed on each received
15 symbol from the demodulator. For satellite, cable and terrestrial transmission
of high data rate signals, such computations need to be performed at very high
rates. Furthermore, in a modem/decoder operating over different channels
with different (but related) coding schemes, the cost of computing the branch
metrics becomes excessive in terms of lookup table memory or actual
20 hardware to perform these computations.

In the case of a satellite transmission channel, it is customary to
transmit some particular punctured quaternary phase shift keyed (QPSK) code
known to the receiver's convolutional decoder. In the case of a terrestrial or
cable transmission channel, some particular pragmatic trellis code (such as
25 quadrature amplitude modulation (QAM), phase amplitude modulation (PAM))

or phase shift keyed (PSK) code) known to the receiver's convolutional decoder. For instance, the prior art discloses the use of a pragmatic trellis code as a practical code for QAM transmission of high definition television (HDTV).

5 In the past, the receiver including a branch metric computer for a Viterbi-algorithm based convolutional decoder was typically designed to operate with only a single predetermined type of

convolutional code. However, it is likely that multi-channel digital television receivers will enter the mass-produced market in the near future and, over time, replace currently-used analog television receivers. Direct broadcast satellite transmission to television receivers is already available in addition to terrestrial and cable transmission thereto. Therefore, it is desirable that the convolutional decoders of such multi-channel digital television receivers be selectively responsive to the type of code (either punctured or pragmatic trellis, as the case may be) and the type of modulation (PSK including both QPSK and 8-PSK, PAM or QAM, as the case may be) of the channel then being received by the multi-channel digital television receiver. Further, mass-produced television receivers should be designed with reduction in cost and complexity in mind.

The inventor has recognized that a single signal processing device can advantageously accommodate multiple demodulation and decoding functions within the context of a digital television signal processing system, for example. In accordance with the principles of the invention, disclosed digital signal processing apparatus provides selective demodulation and decoding elements incorporating different types of demodulation and decoding functions. As a result, a single signal processing network may demodulate and decode signals of different signal format such as satellite, terrestrial and cable television signals, for example.

In a system for receiving a modulated video signal, from multiple types of transmission channels, apparatus in accordance with the principles of the present invention provides a demodulated and decoded output signal. The received video signal is representative of compressed digital video information such as television picture information, and is encoded in one of a plurality of coding formats. The received video signal is also modulated in one of a plurality of modulation formats.

The apparatus includes a demodulator for selectively demodulating the received video signal modulated in one of the plurality of modulation formats to provide a demodulated signal.

The apparatus also includes a decoder for selectively decoding the demodulated signal coded in one of the plurality of coding formats.

5 In accordance with a feature of the invention, the demodulator selectively demodulates the video signal modulated by Pulse Amplitude Modulation (PAM), Quadrature Amplitude Modulation (QAM) or Phase Shift Keying (PSK).

10 In accordance with another feature of the invention the selective decoder decodes the demodulated signal coded in trellis or punctured code format.

In a further feature of the invention, the selective decoder decodes the demodulated signal with a code rate selected from a plurality of code rates.

15 Illustratively, the decoder of the present invention is a convolutional decoder inclusive of a branch metric computer and a Viterbi decoder. In a first embodiment, this branch metric computer may be selectively programmed to operate with any of QPSK punctured-coded and a plurality of PAM or QAM higher alphabet pragmatic trellis-coded I and Q signal inputs thereto. In
20 a second embodiment, this branch metric computer may be additionally selectively programmed to also operate with 8-PSK trellis-coded I and Q signal inputs thereto.

25 Illustratively, the branch metric computer has 2^x -bit I and 2^x -bit Q signal inputs, and comprises (1) a RAM having an effective depth of 2^x storage locations and a width sufficient to store 4-m bit wide entries of at least one preloaded I-defining and one Q-defining lookup tables at each storage location, (2) a group of at least four summers, and (3) means for forwarding the respective sum outputs from four summers of the group to the
30 Viterbi decoder of the convolutional decoder.

In the second embodiment, the width of the RAM is sufficient to store 4-m bit wide entries of two preloaded I-defining and two Q-defining lookup tables at each storage location; the group of at least four summers comprises eight
35 summers organized into first and second sets of four summers; and the means for forwarding the respective sum outputs from

four summers of the group to the Viterbi decoder of the convolutional decoder includes four comparators with each of them forwarding to the Viterbi decoder the lesser sum output from corresponding ones of the summers of the first and second sets.

FIGURE 4 is a block diagram of the structural elements of the branch metric computer shown in FIGURE 3; and

FIGURE 4a illustrates the functional organization of the branch metric computer's structural elements shown in FIGURE 4.

As shown in FIGURE 1, multi-channel compressed-digital television receiver 100 is capable of selectively receiving digitally-encoded television data transmitted over each of a plurality of different channels. These plurality of channels include satellite transmission channel 102, which transmits digitally-encoded television data from forward-error-corrected television transmitter 104; terrestrial transmission channel 106, which

transmits digitally-encoded television data from forward-error-corrected television transmitter 108; and cable transmission channel 110, which transmits digitally-encoded television data from forward-error-corrected television transmitter 112. As known in the art, forward-error-correction at the transmitter typically comprises convolutional encoding of successively-transmitted symbol packets of already encoded compressed-digital television data.

As further known in the art, while QSPK-based punctured codes are typically employed for transmission of convolutional encoded data over a satellite channel, higher alphabet (i.e., 8, 16, 32, 64, 128 and 256) $n/n+1$ pragmatic trellis codes are typically employed for PAM, PSK or QAM based transmission of convolutional encoded data over terrestrial or cable channels. Therefore, it is required that multi-channel receiver 100 incorporates a convolutional decoder that is capable of decoding any particular one of QSPK-based punctured or PAM, PSK or QAM based higher alphabet $n/n+1$ pragmatic trellis codes, depending on the selected one of the multi-channels then being received.

More specifically, multi-channel receiver 100 comprises digital processing apparatus which, as shown in FIGURE 2, includes receiver convolutional decoder 200 and receiver demodulator 202 which, as known in the art, applies each of a series of successively-received convolutionally-encoded symbol packets as the signal input data to receiver convolutional decoder 200. Each successively-received symbol packet of this data defines a point in the in-phase (I), quadrature-phase (Q) plane. The digital processing apparatus of multi-channel receiver 100 further comprises a microcontroller which includes microcontroller interface 204 for applying a control input to receiver convolutional decoder 200.

The relationship among the structural elements of receiver convolutional decoder 200 employed by the present invention, and the control of these elements by external microcontroller interface 204, is shown in FIGURE 3. As shown in FIGURE 3, the structural elements of receiver convolutional decoder 200 include

synchronization circuitry 300, dummy data insertor 302, branch metric computer 304, Viterbi decoder 306, convolutional encoder 308, trellis demapper 310, delay logic 312, synchronization monitor 314 and select means 316. Microcontroller interface 204
5 provides a list of specifications to the aforesaid structural elements which configures the operation of the convolutional encoder as either a decoder for punctured codes or, alternatively, as a decoder for trellis codes. FIGURES 3a and 3b, respectively, show the manner in which the elements of the convolutional
10 encoder shown in FIGURE 3 are (1) configured for operation as a decoder for punctured codes or (2) configured for operation as a decoder for trellis codes.

The output data from demodulator 202 is applied as I,Q input data to synchronization circuitry 300. For illustrative
15 purposes, it is assumed that each of the I and Q data is defined by 6 bits (i.e., the input data is applied over a total of 12 parallel input conductors). This permits each of $64 \times 64 = 4096$ distinct points in the I,Q plane to be defined by the 6-bit I and 6-bit Q components of the 12-bit input data. Synchronization circuitry
20 300 also receives clock and clock-enable (Clk Enb) inputs thereto. In addition, synchronization circuitry 300 both receives control data from microcontroller interface 204 and supplies data thereto, and is directly coupled to synchronization monitor 314.

Each of elements 302, 304, 306, 308 and 310 has control
25 data applied thereto from microcontroller interface 204. Further, although not shown in FIGURE 3, the clock is applied to these elements. Properly synchronized I and Q data is forwarded from synchronization circuitry 300 through dummy data insertor 302 to branch metric computer 304 in response to data input clock
30 enable (DICE) and data output clock enable (DOCE). Further, the properly synchronized I and Q data is forwarded through delay logic 312 to trellis demapper 310 and synchronization monitor 314.

Dummy data insertor 302 is primarily used for punctured
35 codes and is responsible for the insertion of the dummy data corresponding to a specified deletion map for such punctured

codes. For trellis codes, dummy data insertor 302 merely passes through its input data to its output. The choice of code and the corresponding deletion map are conveyed to dummy data insertor 302 via microcontroller interface 204. Dummy data insertor 302
 5 clocks data out with an internal clock at a rate which depends on the coding scheme employed. Since the input and output data rates are different (for punctured codes), the data input clock enable (DICE) and the data output clock enable (DOCE) signals are unique. The DICE signal is the clock enable from receiver
 10 demodulator 202, while the DOCE signal is generated internally in dummy data insertor 302 (and is derived from the clock signal). Specifically, dummy data insertor 302 consists of a FIFO storage mechanism, a write clock to write in the soft decision samples in appropriate locations, and a read clock (which operates at a rate
 15 higher than the write clock and depends on the punctured coding used for its clocking rate) to read out the data for branch metric computations. The dummy samples are also inserted in appropriate locations before being read out.

Branch metric computer 306 (the details of which are
 20 discussed below in FIGURES 4 and 4a) derives 4 separate 5-bit outputs in response to each of successively-received symbol packets. These 4 separate 5-bit outputs and the DOCE signal from branch metric computer 306 are applied as inputs to Viterbi decoder 306. Viterbi decoder 306, which is a Rate $R=1/2$,
 25 constraint length $k=7$ decoder, performs the Viterbi algorithm for punctured and trellis codes, wherein the 5-bit metric inputs from branch metric computer 306 are used to update the states and to make bit decisions. Viterbi decoder 306 employs add-compare-select (ACS) means, path metric storage means, and the memory
 30 for the survivor paths at each level in the trellis. In addition, Viterbi decoder 306 also takes care of metric renormalizations to avoid a buildup and overflow of the accumulated metrics.

A 1-bit output from Viterbi decoder 306 is applied as an input to convolutional encoder 308. For trellis and punctured
 35 codes, convolutional encoder 308 serves to regenerate the best estimates of the two transmitted of the rate $1/2$ embedded code.

The output from encoder 308 is also applied to synchronization monitor 314 for use in checking the synchronization status of punctured codes. In addition, the 1-bit output from Viterbi decoder 306 is applied as an input to select means 316.

5 The 2-bit output from convolutional encoder 308 is applied to trellis demapper 310, which is responsible for making symbol decisions for the trellis-coded mode of operation shown in FIGURE 3b. In the trellis coded mode of operation, trellis demapper 310 uses the 2-bit output from convolutional encoder 308 for subset
10 selection together with the delayed I and Q received symbol data forwarded thereto through delay logic 312 to make these symbol decisions. A 6-bit output from trellis demapper 310 is applied as an input to both synchronization monitor 314 and select means 316.

15 Delay logic 312 accounts for the delay introduced by Viterbi decoder 306/encoder 308 and associated circuitry and synchronizes the data stream at the output of the encoder with the received symbol stream. Control input through microcontroller interface 204 selects one of 4 possible path memory lengths of
20 Viterbi decoder 306 which is also used to appropriately select the delay time in delay logic 312.

 Synchronization monitor 314, which is coupled to synchronization circuitry 300, the output from trellis demapper 310, encoder 308, the output from delay logic 312 and
25 microcontroller interface 204, uses the branch metric information in conjunction with an observation interval specification from microcontroller interface 204 to decide the synchronization status. It also provides information to synchronization circuitry 300 for optional automatic synchronization. In an automatic
30 synchronization mode of operation, the internal synchronization circuitry is employed to perform the synchronization function. Alternatively, the synchronization could be performed from external circuitry. Synchronization monitor 314 is also used to provide a signal to the demodulator for resolving phase
35 ambiguities. This signal is used for only the purpose of accounting for phase ambiguities in receiver demodulator 202. Further,

synchronization monitor 314 supplies a demodulated synchronization signal for use by downstream components of receiver 100.

Select means 316, which receives the 1-bit output of Viterbi decoder 306 and the 6-bit output of trellis demapper 310 applied as inputs thereto, forwards all of these 7 bits to its output when the convolutional decoder is operating in its trellis-code mode and forwards only the 1 bit from the output of Viterbi decoder 306 to its output when the convolutional decoder is operating in its punctured-code mode. This output data along with a clock and a DOCE signal are supplied from select means 316 for use by downstream components of receiver 100.

The structure of branch metric computer 304 comprises random access memory (RAM) 400, Memory banks 0 & 1 I and Q summers 402 and memory banks 0 & 1 I and Q comparators 404. RAM 400 may also be a read-only memory. RAM 400 is preloaded during an initialization phase with programmable, precomputed I and Q lookup tables from microcontroller interface 204 applied as a control input thereto. In response to I and Q signals forwarded from dummy data insertor 302 (which depunctures QPSK-based punctured coded symbols) to RAM 400 as signal inputs thereto, selected ones of the I and Q entries of these lookup tables are read out as outputs from RAM 400 and applied as inputs to memory banks 0 & 1 I and Q summers 402. The output from memory banks 0 & 1 I and Q summers 402 is applied as an input to memory banks 0 & 1 I and Q comparators 404, and the output from memory banks 0 & 1 I and Q comparators 404 is forwarded as an input to Viterbi decoder 306.

More specifically, as functionally shown in FIGURE 4a, RAM 400 is organized into metric memory bank 0 and metric memory bank 1. Memory bank 0 is made up of a first pair of subsets comprising first I subset 00 and first Q subset 00; a second pair of subsets comprising second I subset 01 and second Q subset 01; a third pair of subsets comprising third I subset 11 and third Q subset 11; and a fourth pair of subsets comprising fourth I subset 10 and fourth Q subset 10. Memory bank 1 is also made up of 4

similar pairs of I and Q subsets, thereby providing a total of 8 pairs. of I and Q subsets for RAM 400. Each of the 8 I subsets receives the I signal input to RAM 400 and each of the 8 Q subsets receives the Q signal input to RAM 400. In general, each of the I and Q signal inputs is an x-bit signal (specifically assumed in the illustrative FIGURE 3 example to be a 6-bit signal). Each of the 8 I subsets derives an m-bit signal output (illustratively assumed to be a 4-bit signal output) and each of the 8 Q subsets derives an m-bit signal output.

10 All of the 8 separate I and Q m-bit signal outputs from RAM 400 are forwarded as inputs to the respective summers of memory banks 0 & 1 I and Q summers 402. Specifically, the two outputs from the first pair of subsets of bank 0 are applied as first and second inputs to summer 402-1; the two outputs from the second pair of subsets of bank 0 are applied as first and second inputs to summer 402-2; the two outputs from the third pair of subsets of bank 0 are applied as first and second inputs to summer 402-3; the two outputs from the fourth pair of subsets of bank 0 are applied as first and second inputs to summer 402-4; the two outputs from the first pair of subsets of bank 1 are applied as first and second inputs to summer 402-5; the two outputs from the second pair of subsets of bank 1 are applied as first and second inputs to summer 402-6; the two outputs from the third pair of subsets of bank 1 are applied as first and second inputs to summer 402-7, and the two outputs from the fourth pair of subsets of bank 1 are applied as first and second inputs to summer 402-8. A separate (m+1)-bit output signal (i.e., 5-bit signal in the assumed case) is derived from each of these 8 summers.

30 All of the 8 separate (m+1)-bit output signals from the summers are forwarded as inputs to the respective comparators of memory banks 0 & 1 I and Q comparators 404. Specifically, the outputs from summers 402-1 and 402-5 are applied as first and second inputs to comparator 404-1; the outputs from summers 402-2 and 402-6 are applied as first and second inputs to comparator 404-2; the outputs from summers 402-3 and 402-7

are applied as first and second inputs to comparator 404-3, and the outputs from summers 402-4 and 402-8 are applied as first and second inputs to comparator 404-4. Each of these comparators passes to its output the lower-valued one of its two $(m+1)$ -bit
 5 inputs. The respective outputs from the 4 comparators constitute the output from branch metric computer 304 (i.e., four 5-bit outputs in the assumed case) which are applied as inputs to Viterbi decoder 306.

Structurally, RAM 400 is of a fixed bit storage size having an
 10 effective depth of 2^x storage locations (i.e., corresponding to locations 1 through 64 in the assumed example in which $x=6$). Each of the I and Q signal inputs to bank 0 and each of the I and Q signal inputs to bank 1 of RAM 400 has a separate lookup table associated therewith. The width of RAM 400 is sufficient to store
 15 four $4m$ -bit wide ($m=4$ in the assumed example) precomputed lookup tables, each of which is made up of 2^x entries, that have been supplied thereto over the programmable I and Q lookup table control input. Thus, the bit-storage size of RAM 400 is
 (2^x)(4) (4m) or, in the assumed case, a bit-storage size of 4096
 20 bits. In the case of implementing a punctured QPSK-based code, a simple technique is to pass the maximum I and Q values and store the punctured metrics in appropriate locations in the lookup tables. This necessitates a possible clipping of the actual I and Q data, but can be handled in the front end of decoder 200. Further,
 25 the lookup tables can be programmed to permit a desired maximum branch metric value by disregarding certain lesser significant I and Q input data.

As discussed above, branch metric computer 304 is a component of Viterbi-algorithm based convolutional decoder 200
 30 which is used to decode QPSK-based punctured codes for satellite modem operation over a noisy channel and higher alphabet (16, 32, 64, 128 and 256 PAM or QAM or 8-PSK) based rate $n/n+1$ pragmatic trellis codes for terrestrial or cable operation over a noisy channel. As known, due to channel noise, the location point
 35 of a received demodulated symbol in the I,Q plane will be displaced from its transmitted location point in the I,Q plane. The

location point of each successively-received demodulated symbols in the I,Q plane is defined with a resolution of $22 \times$ (i.e., $64 \times 64 = 4096$ in the assumed example) by the I and Q signal inputs to RAM 400. The important fact to note about RAM 400 is that its
 5 memory requirement is independent of alphabet size.

The 4 m-bit (4-bit in the assumed case) entries of the respective I and Q lookup tables of the 0 bank corresponding to a currently-received demodulated symbol define the respective I and Q components of the respective distances in the I, Q plane of
 10 the location points of each of 4 specified valid symbol constellation subsets surrounding the location points of the currently-received demodulated symbol from the location point of this currently-received demodulated symbol.

In the QPSK case, (in which each subset location point
 15 defines only a single symbol location point) and in the higher alphabet PAM or QAM cases (in which each subset location point corresponds to the locations of a subset of $1/4$ of the symbols in that alphabet needed by Viterbi decoder 206, with trellis demapper 310 choosing the correct point within the subset based
 20 on delayed, received data applied thereto), a single I component and a single Q component are sufficient to define the four subsets without ambiguity. Therefore, in these cases only bank 0 of RAM 400 is required. However, in the case of 8-PSK, a single I component and a single Q component used independently
 25 are insufficient to define four symbol subsets without ambiguity. Therefore, in the 8-PSK case, bank 0 is used to define 0° , 90° , 180° , 270° location points and bank 1 (which operates in a manner similar to that of above-described bank 0) is used to define 45° , 135° , 225° , 315° location points. Comparators 404-1 to
 30 404-4, employing data derived from both bank 0 and bank 1 of RAM 400, are used to resolve this ambiguity in a manner described below.

Summers 402-1 to 402-8 employ the I and Q components of distance to valid constellation location points read out of RAM 400
 35 to compute the so-called Manhattan distance ($I + Q$) defined by each of the 8 subsets. The Manhattan distance assignment is not

the true Euclidean distance $(I^2 + Q^2)^{1/2}$, but a distance measure that weights closer points in the I,Q plane more heavily than points in the I,Q plane further away from the received symbol location point. The Manhattan distance metric uses the sum of the
5 differences between the I and Q coordinates of two points in the I, Q two-dimensional space. This distance measure is monotonic with distance, but does weigh points differently depending on their position with respect to the point to which the distance is being computed. However, since the use of the Manhattan distance
10 metric makes the operations on the I and Q coordinates to be decoupled and independent, it drastically reduces the memory requirements of for storing the possible distances from any received location point to a valid constellation location point.

Each of comparators 404-1 to 404-4 is designed to pass the
15 smaller of the two metrics applied from bank 0 and bank 1 as inputs thereto. Thus, in the case of an 8-PSK based code, each of comparators 404-1 to 404-4 will derive as an output either the metric input from bank 0 or from bank 1, depending upon which is smaller. However, in the case of QPSK, PAM or QAM based
20 codes, the I and Q lookup tables stored in bank 1 of RAM 400 are programmed to be filled with maximum-valued metrics so that they are effectively inactive and, therefore, each of comparators 404-1 to 404-4 passes the metric chosen out of bank 0 of RAM 400. In a multi-channel receiver not designed to receive an 8-PSK
25 based code, both these comparators and memory bank 1 of RAM 400 may be eliminated (thereby reducing the required memory storage capacity of RAM 400 in half).

Although the convolutional decoder disclosed herein is primarily for use in a multi-channel television receiver for
30 receiving punctured-coded or pragmatic trellis-coded compressed-digital television data, it is not intended that the type of coded data capable of being decoded by the disclosed convolutional decoder be limited to only television data, but may be employed by any other type of coded data capable of being
35 decoded by the disclosed convolutional decoder.

In addition to being suitable for use in a receiver of satellite, terrestrial and cable television data as mentioned previously, the disclosed decoder apparatus is also suitable for use in other applications including telephone, direct microwave and fiber optic
5 transmission.

Claims:

1. In a system for receiving a modulated signal from multiple types of transmission channels, said signal being representative of compressed digital data coded in one of a plurality of coding formats and exhibiting one of a plurality of modulation formats, a method comprising the steps of:

selecting a modulation format for demodulation from among modulation formats including QAM and PSK;

demodulating said modulated signal according to said selected modulation format to produce a demodulated signal;

selecting a coding format for decoding from among said plurality of coding formats; and

decoding said demodulated signal according to said selected coding format to produce a demodulated and decoded signal.

2. In a system for receiving a modulated signal from multiple types of transmission channels, said signal being representative of compressed digital data coded in one of a plurality of coding formats and exhibiting one of a plurality of modulation formats, a method comprising the steps of:

selecting a modulation format for demodulation from among said plurality of modulation formats;

demodulating said modulated signal according to said selected modulation format to produce a demodulated signal;

selecting a coding format for decoding from among coding formats including punctured coded and trellis coded formats; and

decoding said demodulated signal according to said selected coding format to produce a demodulated and decoded signal.

3. A method according to claim 2, further including the step of selecting a modulation format for demodulation from among modulation formats including QAM and PSK.

4. A method according to claim 1 or claim 3, further including the step of selecting a modulation format for demodulation from among modulation formats further including PAM.

5. A method according to claim 1 or claim 3, wherein said PSK modulation format is a QPSK modulation format.

6. A method according to claim 1 or claim 2, wherein said step of selecting a modulation format includes the step of selecting between multiple types of transmission channels including at least two channels from among satellite, cable and terrestrial channels.
